Abstract

Varying coefficient regression is a flexible technique for modeling data where the coefficients are functions of some effect-modifying parameter, often time or location in a certain domain. While there are a number of methods for variable selection in a varying coefficient regression model, the existing methods are mostly for global selection, which includes or excludes each covariate over the entire domain. Presented here is a new local adaptive grouped regularization (LAGR) method for local variable selection in spatially varying coefficient linear and generalized linear regression. LAGR selects the covariates that are associated with the response at any point in space, and simultaneously estimates the coefficients of those covariates by tailoring the adaptive group Lasso toward a local regression model with locally linear coefficient estimates. Oracle properties of the proposed method are established under local linear regression and local generalized linear regression. The finite sample properties of LAGR are assessed in a simulation study and for illustration, the Boston housing price data set is analyzed.

Keywords: adaptive Lasso, local generalized linear regression, local polynomial regression, nonparametric, regularization method, varying coefficient model

1. Introduction

Whereas the coefficients in traditional linear regression are scalar constants, the coefficients in a varying coefficient regression (VCR) model are functions - often *smooth* functions - of some effect-modifying parameter (Cleveland and Grosse, 1991; Hastie and Tibshirani, 1993). Here we treat the case of a VCR model on a spatial domain where the spatial location is a two-dimensional effect-modifying parameter. Current practice for VCR models relies on global model selection to decide which variables should be included in the model, meaning that covariates are selected for inclusion or exclusion over the entire domain. Various methods have been developed by using, for example, P-splines (Antoniadas et al., 2012), basis expansion (Wang et al., 2008), and local regression (Wang and Xia, 2009). Since the coefficients vary in a VCR model, in principle there is no reason that the best model must use the same set of covariates everywhere on the domain - that is, some of the coefficients may be zero in part of the domain. New methodology is developed here for guiding the decision of which covariates belong in the VCR model at any location, termed local variable selection, as the literature on how to do so is currently scarce. Such new methodology provides for more flexible variable selection in regression models with coefficients that vary in space.

Specifically, local adaptive grouped regularization (LAGR) is developed here as a novel method of local variable selection at a given location in the domain of a VCR model. The method of LAGR applies to VCR models where the coefficients are estimated using locally linear kernel smoothing. Kernel smoothing for nonparametric regression is described in detail in Fan and Gijbels (1996). The extension to estimating VCR models is made by Fan and Zhang (1999) for a VCR model with a univariate effect-modifying parameter, and by Sun et al. (2014) for a two-dimensional effect-modifying parameter in a spatial VCR with autocorrelation. These methods mitigate the boundary effect by estimating the coefficients as local polynomials of odd degree (usually locally linear) (Hastie and Loader, 1993). However, none of these authors addressed local variable selection. In this work, we focus on local variable selection with a two-dimensional effect-modifying parameter and discuss the effect

of dimensionality on the results.

For standard linear regression models, the least absolute shrinkage and selection operator (Lasso) is a regularization method that simultaneously selects covariates for the regression model and shrinks the coefficient estimates toward zero (Tibshirani, 1996). However, the Lasso can be inconsistent for variable selection and inefficient for coefficient estimation (Zou, 2006). The adaptive Lasso (AL) is a refinement of the Lasso that produces consistent estimates of the coefficients and has been shown to have appealing properties for variable selection, which under suitable conditions include the “oracle” property of asymptotically including exactly the correct set of covariates and estimating their coefficients as well as if the correct covariates were known in advance (Zou, 2006). For data where the observed covariates fall into mutually exclusive groups that are known in advance, the adaptive group Lasso has similar oracle properties to the adaptive Lasso but selects groups rather than individual covariates (Yuan and Lin, 2006; Wang and Leng, 2008). An innovation here is to develop an adaptive group Lasso for local variable selection and coefficient estimation in a locally linear regression model, where each group consists of a single covariate and its interactions with the effect-modifying parameter. Further, we consider both varying coefficient linear regression for Gaussian response and varying coefficient generalized linear regression for responses that are not necessarily Gaussian. We show that the proposed LAGR method possesses the oracle properties of asymptotically selecting exactly the correct local covariates and estimating their local coefficients as accurately as would be possible if the identity of the nonzero coefficients for the local model were known in advance.

The remainder of this paper is organized as follows. The kernel-based estimation of a VCR model is described in Section 2. The proposed LAGR technique for varying coefficient linear regression and its oracle properties are presented in Section 3. In Section 4, LAGR is applied to the Boston housing price dataset, followed by conclusions and discussion in Section 7. Technical proofs are given in the appendices.

2. Varying Coefficient Regression

Throughout the paper, we work with the generalized linear model (GLM). The response of a GLM can come from any distribution in the exponential family, so the familiar linear regression model is included as a special case.

2.1. Varying coefficient model

The response $Y(s)$, covariates $\mathbf{X}(s)$, and coefficients $\boldsymbol{\beta}(s)$ in a VCR model are indexed by the location parameter s . Let δ be the dimension of the location parameter (e.g., $\delta = 1$ for a coefficients that vary with time). Assume n observations of the response and the covariates at locations s_1, \dots, s_n and let $Y_i = Y(s_i)$, $\mathbf{X}_i = \mathbf{X}(s_i)$, and $\boldsymbol{\beta}_i = \boldsymbol{\beta}(s_i)$. The generalized linear model (GLM) with varying coefficients is written

$$\begin{aligned} E[Y(s)|\mathbf{X}(s)] &= \mu(s) \\ \eta(s) &= g(\mu(s)) = \mathbf{X}'(s)\boldsymbol{\beta}(s) \\ \text{var}[Y(s)|\mathbf{X}(s)] &= \phi V(\mu(s)) \end{aligned}$$

where $g(\cdot)$, $V(\cdot)$, and ϕ are, respectively, the link function, variance function, and dispersion parameter of the response family. For simplicity of notation, assume the canonical link function (McCullagh and Nelder, 1989).

2.2. Local polynomial regression

In the context of nonparametric regression, the boundary-effect bias can be reduced by local polynomial modeling, usually in the form of a locally linear model (Fan and Gijbels, 1996). At each estimation location s_i , the coefficient functions are approximated by Taylor's expansion as locally linear functions of the location parameter

$$\boldsymbol{\beta}(s) = \boldsymbol{\beta}(s_i) + \nabla \boldsymbol{\beta}(s_i)(s - s_i) + o(|s - s_i|). \quad (1)$$

The locally linear approximation is implemented by augmenting the matrix $\mathbf{X}(s)$ with interactions between the covariates and the location parameter. Letting $\mathbf{Z}(s) = (\mathbf{X}_i \text{ diag}\{s - s_i\}_{i=1}^n \cdot \mathbf{X}_i)$ and $\boldsymbol{\zeta}(s) = (\boldsymbol{\beta}(s)^T, \nabla \boldsymbol{\beta}(s)^T)^T$, the linear predictor of the local GLM is $\hat{\eta}_i = \mathbf{Z}_i \hat{\boldsymbol{\zeta}}_i$.

2.3. Coefficient estimation via local quasi-likelihood

The quasi-likelihood $Q(\mu, Y)$ is an approximation to the full log likelihood. Its derivative the quasi-score function is $q(\mu, Y) = (y - \mu)\{V(\mu)\}^{-1}$, which is a function of the linear predictor η through the link and variance functions. Let $\boldsymbol{\zeta} = (\boldsymbol{\zeta}_1, \dots, \boldsymbol{\zeta}_n)^T$ denote a matrix of the local coefficients at all observation locations $\mathbf{s}_1, \dots, \mathbf{s}_n$. The vector $\boldsymbol{\zeta}$ has length $(\delta + 1) \times n$, but there are only n observations. Thus, the total quasi-likelihood is not identifiable and it is not possible to directly maximize $\sum_{i=1}^n Q(\hat{\mu}_i, y_i)$.

When the coefficient functions are smooth, though, the coefficients $\boldsymbol{\zeta}(s)$ at location s can be approximated by the coefficients $\boldsymbol{\zeta}(t)$, where t is within some neighborhood of s . This intuition is formalized by the following local quasi-likelihood at location $s \in \mathcal{D}$:

$$\ell(\boldsymbol{\zeta}(s)) = \sum_{i=1}^n K_h(\|\mathbf{s} - \mathbf{s}_i\|) Q(g^{-1}(\mathbf{Z}_i^T \boldsymbol{\zeta}(s)), Y_i). \quad (2)$$

where $\mathbf{Z}_i = \{\mathbf{Z}(s)\}_i$, h is a bandwidth parameter, $\|\cdot\|$ is the ℓ_2 -norm, and $K_h(\|\mathbf{s} - \mathbf{s}_i\|) = h^{-\delta} K(h^{-1}\|\mathbf{s}_i - \mathbf{s}_i'\|)$ for $i = 1, \dots, n$ are local weights from a kernel function. For instance, the Epanechnikov kernel is defined as (Samiuddin and el Sayyad, 1990)

$$K(x) = (3/4)(1 - x^2) \text{ if } x < 1 \text{ and } 0 \text{ otherwise.} \quad (3)$$

The local quasi-likelihood (6) is maximized to obtain an estimate $\tilde{\boldsymbol{\zeta}}(s)$ of the local coefficients at s . Since the quasi-likelihood is concave, the maximum is achieved where the local quasi-

score is zero:

$$q\left(\tilde{\boldsymbol{\zeta}}(\mathbf{s})\right)=\sum_{i=1}^n K_h\left(\left\|\mathbf{s}-\mathbf{s}_i\right\|\right)\left(y_i-\tilde{\mu}\left(\mathbf{s}_i ; \mathbf{s}\right)\right)\left\{V\left(\tilde{\mu}\left(\mathbf{s}_i ; \mathbf{s}\right)\right)\right\}^{-1} \mathbf{z}_i=\mathbf{0} . \quad (4)$$

where $\tilde{\mu}\left(\mathbf{s}_i ; \mathbf{s}\right)=g^{-1}\left(\mathbf{z}_i^T \tilde{\boldsymbol{\zeta}}(\mathbf{s})\right)$ is the mean at location s_i evaluated with the estimated coefficients $\tilde{\boldsymbol{\zeta}}(\mathbf{s})$ at location s . The asymptotic distribution of the local coefficients in a varying-coefficient GLM is (Cai et al., 2000):

$$\left\{n h^{\delta} f(s)\right\}^{1 / 2}\left[\tilde{\boldsymbol{\beta}}(s)-\boldsymbol{\beta}(s)-\left(1 / 2\right) \kappa_0^{-1} \kappa_2 h^{\delta} \nabla^2 \boldsymbol{\beta}(s)\right] \\ \xrightarrow{D} N\left(\mathbf{0}, \kappa_0^{-2} \nu_0 \boldsymbol{\Gamma}(s)^{-1}\right) .$$

where $\boldsymbol{\Gamma}(s)=E\left\{\rho(s, \mathbf{X}(s)) \mathbf{X}(s) \mathbf{X}(s)^T \mid s\right\}$, $\rho(s, \mathbf{z})=\left[g_1\left(\mu(s, \mathbf{z})\right)\right]^2 \text { Var }\{Y(s) \mid \mathbf{X}(s), s\}$, $g_1(\cdot)=g_0'(\cdot) / g'(\cdot)$, and $g_0(\cdot)$ is the canonical link function. So when the canonical link is used, $\rho(s, \mathbf{z})=V\left(\mu(s, \mathbf{z})\right)$.

So for any given s , the estimated local coefficients $\tilde{\boldsymbol{\beta}}(s)=\left(\tilde{\zeta}_1(s), \ldots, \tilde{\zeta}_p(s)\right)^T$ converge in probability at the optimal rate of $O\left(n^{-1 / 3}\right)$ and are asymptotically normally distributed. The bias of the local coefficient estimates is proportional to the second derivatives of the true coefficient functions.

3. Local Variable Selection with LAGR

3.1. LAGR Penalized Local Likelihood

Estimating the local coefficients by (??) has traditionally relied on variable selection *a priori*; that is, a set of covariates is pre-determined. Here we develop a new method of penalized regression to simultaneously select covariates locally and estimate the corresponding local coefficients. For this purpose, each raw covariate is grouped with its covariate-by-location interactions. That is, $\boldsymbol{\zeta}_{(j)}(\mathbf{s})=\left(\beta_j(\mathbf{s}), \nabla_u \beta_j(\mathbf{s}), \nabla_v \beta_j(\mathbf{s})\right)^T$ for $j=1, \ldots, p$. The proposed

penalty is akin to the adaptive group Lasso (Yuan and Lin, 2006; Wang and Leng, 2008). By the mechanism of the adaptive group Lasso, covariates within the same group are included in or dropped from the model together. The intercept group is left unpenalized.

To select and estimate the local coefficients at location \mathbf{s} , we minimize a penalized local sum of squares at location \mathbf{s} :

$$\mathcal{J}(\boldsymbol{\zeta}(\mathbf{s})) = \mathcal{S}(\boldsymbol{\zeta}(\mathbf{s})) + \mathcal{P}(\boldsymbol{\zeta}(\mathbf{s})), \quad (5)$$

where $\mathcal{S}(\boldsymbol{\zeta}(\mathbf{s}))$ is the locally weighted least squares defined in (??), $\mathcal{P}(\boldsymbol{\zeta}(\mathbf{s})) = \sum_{j=1}^p \phi_j(\mathbf{s}) \|\boldsymbol{\zeta}_{(j)}(\mathbf{s})\|$ is a local adaptive grouped regularization (LAGR) penalty. The LAGR penalty for the j th group of coefficients at location \mathbf{s} is $\phi_j(\mathbf{s}) = \lambda_n \|\tilde{\boldsymbol{\zeta}}_{(j)}(\mathbf{s})\|^{-\gamma}$, where $\lambda_n > 0$ is a local tuning parameter applied to all coefficients at location \mathbf{s} , $\tilde{\boldsymbol{\zeta}}_{(j)}(\mathbf{s})$ is a vector of unpenalized local coefficients for the j th covariate and its interactions with location from (??), and $\gamma > 1$.

Minimization of (5) is by blockwise coordinate descent, where each block is a covariate group (one raw covariate and its interactions with location). A companion software package for estimating $\boldsymbol{\zeta}(\mathbf{s})$ will be made available in R (R Core Team, 2014).

3.2. Oracle Property

At location \mathbf{s} , let there be $p_0(\mathbf{s}) < p$ covariates $\mathbf{X}_{(a)}(\mathbf{s})$ with nonzero local regression coefficients, denoted $\boldsymbol{\beta}_{(a)}(\mathbf{s}) \neq \mathbf{0}$. Without loss of generality, assume the indices of these covariates are $1, \dots, p_0(\mathbf{s})$. The remaining $p - p_0(\mathbf{s})$ covariates $\mathbf{X}_{(b)}(\mathbf{s})$ have coefficients equal to zero, denoted $\boldsymbol{\beta}_{(b)}(\mathbf{s}) = \mathbf{0}$. Denote by $a_n = \max\{\phi_j(\mathbf{s}), j \leq p_0(\mathbf{s})\}$ the largest penalty applied to a covariate group whose true coefficient norm is nonzero, and by $b_n = \min\{\phi_j(\mathbf{s}), j > p_0(\mathbf{s})\}$ the smallest penalty applied to a covariate group whose true coefficient norm is zero. Let $\mathbf{Z}_{(k)}(\mathbf{s})$ be the augmented design matrix for covariate group k , and let $\mathbf{Z}_{(-k)}(\mathbf{s})$ be the augmented design matrix for all the data except covariate group k . Similarly, let $\boldsymbol{\zeta}_{(k)}(\mathbf{s})$ be the augmented coefficients for covariate group k and $\boldsymbol{\zeta}_{(-k)}(\mathbf{s})$ be the aug-

mented coefficients for all covariate groups except k . Let $\nabla\zeta_j(\mathbf{s}) = (\nabla_u\zeta_j(\mathbf{s}), \nabla_v\zeta_j(\mathbf{s}))^T$ and $\nabla^2\zeta_j(\mathbf{s}) = \begin{pmatrix} \nabla_{uu}^2\zeta_j(\mathbf{s}) & \nabla_{uv}^2\zeta_j(\mathbf{s}) \\ \nabla_{vu}^2\zeta_j(\mathbf{s}) & \nabla_{vv}^2\zeta_j(\mathbf{s}) \end{pmatrix}$. Let $\kappa_0 = \int_{\mathbb{R}^2} K(\|\mathbf{s}\|)d\mathbf{s}$, $\kappa_2 = \int_{\mathbb{R}^2} [(1, 0)\mathbf{s}]^2 K(\|\mathbf{s}\|)d\mathbf{s} = \int_{\mathbb{R}^2} [(0, 1)\mathbf{s}]^2 K(\|\mathbf{s}\|)d\mathbf{s}$, and $\nu_0 = \int_{\mathbb{R}^2} K^2(\|\mathbf{s}\|)d\mathbf{s}$. Finally, let \xrightarrow{p} and \xrightarrow{d} denote convergence in probability and distribution, respectively, as $n \rightarrow \infty$.

Assume the following regularity conditions.

- (C.1) The kernel function $K(\cdot)$ is bounded, positive, symmetric, and Lipschitz continuous on \mathbb{R} , and has a bounded support.
- (C.2) The coefficient functions $\beta_j(\cdot)$ for $j = 1, \dots, p$ have continuous second-order partial derivatives at \mathbf{s} .
- (C.3) The covariates $\mathbf{X}(\mathbf{s}_1), \dots, \mathbf{X}(\mathbf{s}_n)$ are random vectors that are independent of $\varepsilon_1, \dots, \varepsilon_n$. Also $\Psi(\mathbf{s}) = E\{\mathbf{X}(\mathbf{s})\mathbf{X}(\mathbf{s})^T|\mathbf{s}\}$ and $\Psi_{(a)}(\mathbf{s}) = E\{\mathbf{X}_{(a)}(\mathbf{s})\mathbf{X}_{(a)}(\mathbf{s})^T|\mathbf{s}\}$ are positive-definite and differentiable at location \mathbf{s} .
- (C.4) $E\{|\mathbf{X}(\mathbf{s})|^3|\mathbf{s}\}$ and $E\{Y(\mathbf{s})^4|\mathbf{X}(\mathbf{s}), \mathbf{s}\}$ are continuous at a given location \mathbf{s} .
- (C.5) The observation locations $\{\mathbf{s}_i\}$ are a sequence of design points on a bounded compact support \mathcal{S} . Further, there exists a positive joint density function $f(\cdot)$ satisfying a Lipschitz condition such that

$$\sup_{\mathbf{s} \in \mathcal{S}} \left| n^{-1} \sum_{i=1}^n [r(\mathbf{s}_i)K_h(\|\mathbf{s}_i - \mathbf{s}\|)] - \int r(\mathbf{t})K_h(\|\mathbf{t} - \mathbf{s}\|)f(\mathbf{t})d\mathbf{t} \right| = O(h)$$

where $f(\cdot)$ is bounded away from zero on \mathcal{S} , $r(\cdot)$ is any bounded continuous function, and $K_h(\cdot) = K(\cdot/h)/h^2$.

$$(C.6) \quad h = O(n^{-1/6}).$$

$$(C.7) \quad h^{-1}n^{-1/2}a_n \xrightarrow{p} 0 \text{ and } hn^{-1/2}b_n \xrightarrow{p} \infty.$$

Conditions (C.1)–(C.4) are common in the literature on nonparametric estimation, for instance see conditions (1)–(3) of Sun et al. (2014) and conditions (5) and (6) of Cai et al. (2000). However, the covariates $\mathbf{X}(\mathbf{s}_1), \dots, \mathbf{X}(\mathbf{s}_n)$ were assumed to be *iid* in Sun et al. (2014), which is not required here. The existence of $\Psi(\cdot)$ is needed for the existence of the limiting distribution of $\hat{\beta}(\mathbf{s})$; its differentiability is used in the Taylor’s expansions. Condition (C.4) is used when bounding the remainder term in the Taylor’s expansions. Condition (C.5) is the same as condition (4) of Sun et al. (2014). Under condition (C.6), the coefficient estimates attain the optimal rate of convergence for bivariate nonparametric regression. Condition (C.7) is needed for establishing the oracle properties, and is a refinement of the condition for the adaptive group Lasso (Wang and Leng, 2008).

In particular, satisfying (C.7) implies an additional restriction on γ , the unpenalized group norm exponent in the LAGR penalty. Under condition (C.7), the local penalty tends to zero on covariates with true nonzero coefficients and to infinity on covariates with true zero coefficients. By (C.7), $h^{-1}n^{-1/2}\lambda_n \rightarrow 0$ for all $j \leq p_0(\mathbf{s})$ and $hn^{-1/2}\lambda_n\|\tilde{\zeta}_{(j)}(\mathbf{s})\|^{-\gamma} \rightarrow \infty$ for all $j > p_0(\mathbf{s})$. We require that λ_n satisfy both assumptions. Suppose $\lambda_n = n^\alpha$. Since $h = O(n^{-1/6})$ and $\|\tilde{\zeta}_{(p)}(\mathbf{s})\| = O(h^{-1}n^{-1/2})$, it follows that $h^{-1}n^{-1/2}\lambda_n = O(n^{-1/3+\alpha})$ and $hn^{-1/2}\lambda_n\|\tilde{\zeta}_{(p)}(\mathbf{s})\|^{-\gamma} = O(n^{-2/3+\alpha+\gamma/3})$. Thus, $(2 - \gamma)/3 < \alpha < 1/3$, which can only be satisfied for $\gamma > 1$.

Further, let $\phi_j(\mathbf{s}) = \lambda_n\|\tilde{\zeta}_{(j)}(\mathbf{s})\|^{-\gamma}$, where $\lambda_n > 0$ is a the local tuning parameter applied to all coefficients at location \mathbf{s} and $\tilde{\zeta}_{(j)}(\mathbf{s})$ is the vector of unpenalized local coefficients. In addition to the definitions and conditions of Section 3.2, let

$$\mathbf{\Gamma}_{(a)}(\mathbf{s}) = E\left\{\rho(\mathbf{s}, \mathbf{X}_{(a)}(\mathbf{s})) \mathbf{X}_{(a)}(\mathbf{s})\mathbf{X}_{(a)}(\mathbf{s})^T | \mathbf{s}\right\}$$

and assume the following regularity conditions:

(C.8) The functions $g'''(\mathbf{s})$, $\nabla\mathbf{\Gamma}(\mathbf{s})$, $\nabla\mathbf{\Gamma}_{(a)}(\mathbf{s})$, $V(\mu(\mathbf{s}, \mathbf{z}))$, and $V'(\mu(\mathbf{s}, \mathbf{z}))$ are continuous at \mathbf{s} .

(C.9) The function $(\partial^2/\partial\mu^2) Q(g^{-1}(\mu), y) < 0$ for $\mu \in \mathbb{R}$ and y in the range of the response.

These additional conditions are not uncommon in the nonparametric regression literature (see, e.g., conditions (1) and (2) of Cai et al. (2000)). Condition (C.8) is needed for the Taylor's expansion of the local quasi-likelihood. Condition (C.9) assures that the local quasi-likelihood is concave and has a unique maximizer.

Theorem 1 (Asymptotic normality). *Under (C.1)–(C.10),*

$$\begin{aligned} \{nh^2 f(\mathbf{s})\}^{1/2} \left[\hat{\boldsymbol{\beta}}_{(a)}(\mathbf{s}) - \boldsymbol{\beta}_{(a)}(\mathbf{s}) - (2\kappa_0)^{-1} \kappa_2 h^2 \left\{ \nabla_{uu}^2 \boldsymbol{\beta}_{(a)}(\mathbf{s}) + \nabla_{vv}^2 \boldsymbol{\beta}_{(a)}(\mathbf{s}) \right\} \right] \\ \xrightarrow{d} N(0, \kappa_0^{-2} \nu_0 \boldsymbol{\Gamma}_{(a)}(\mathbf{s})^{-1}) \end{aligned}$$

Theorem 2 (Selection consistency). *Under (C.1)–(C.10), if $j > p_0(\mathbf{s})$,*

$$P \left\{ \|\hat{\boldsymbol{\xi}}_{(j)}(\mathbf{s})\| = \mathbf{0} \right\} \rightarrow 1.$$

By Theorem 1, the LAGR estimates achieve the same asymptotic distribution as if the nonzero coefficients were known in advance. The difference between the Gaussian and GLM cases is that $\sigma^2 \boldsymbol{\Psi}_{(a)}(\mathbf{s})^{-1}$ in the variance term of Theorem ?? has been replaced by $\boldsymbol{\Gamma}_{(a)}(\mathbf{s})^{-1}$ in Theorem 1 because the variance of the response in the GLM case depends on the expectation of the response. Theorem 2 gives the same result for the GLM setting as Theorem ?? does for the Gaussian setting: the true zero coefficients are dropped from the model with probability tending to one. Thus, the oracle properties for the GLM setting are established. The technical proofs are given in Appendix B and the necessary lemmas are provided in the online supplementary materials.

Theorem ?? indicates that the LAGR estimates for true nonzero coefficients have the same asymptotic distribution as a local regression model where the true nonzero coefficients are known in advance. Further, by Theorem ??, the LAGR estimates of true zero coefficients tend to zero with probability one. Together, local variable selection and local coefficient

estimation by LAGR have the oracle property. The technical proofs of Theorems ?? and ?? are given in Appendix A.

3.3. Tuning Parameter Selection

In practical application, it is necessary to select the LAGR tuning parameter λ_n for each local model. A popular approach in other Lasso-type problems is to select the tuning parameter that maximizes a criterion that approximates the expected log-likelihood of a new, independent data set drawn from the same distribution. This is the framework of Mallows' C_p , Stein's unbiased risk estimate (SURE) and Akaike's information criterion (AIC) (Mallows, 1973; Stein, 1981; Akaike, 1973).

These criteria use a so-called covariance penalty to estimate the bias due to using the same data set to select a model and to estimate its parameters (Efron, 2004). We adopt the approximate degrees of freedom for the adaptive group Lasso from Yuan and Lin (2006) and minimize the AIC to select the tuning parameter λ_n . That is, let

$$\begin{aligned}\hat{\text{df}}(\lambda_n; \mathbf{s}) &= \sum_{j=1}^p I\left(\|\hat{\boldsymbol{\zeta}}(\lambda_n; \mathbf{s})\| > 0\right) + d \sum_{j=1}^p \|\hat{\boldsymbol{\zeta}}(\lambda_n; \mathbf{s})\| \|\tilde{\boldsymbol{\zeta}}(\mathbf{s})\|^{-1}, \\ \text{AIC}(\lambda_n; \mathbf{s}) &= \sum_{i=1}^n K_h(\|\mathbf{s} - \mathbf{s}_i\|) \sigma^{-2} \left\{ y_i - \mathbf{z}_i^T \hat{\boldsymbol{\zeta}}(\lambda_n; \mathbf{s}) \right\}^2 + 2\hat{\text{df}}(\lambda_n; \mathbf{s}),\end{aligned}$$

where $I(\cdot)$ is the indicator function, d is the dimension of the effect-modifying parameter, and the local coefficient estimate is written $\hat{\boldsymbol{\zeta}}(\lambda_n; \mathbf{s})$ to emphasize that it depends on the tuning parameter. Here, $d = 2$. More general dimensionality is discussed in Section 6.

4. Data Example

The proposed LAGR estimation method was applied to estimate the coefficients in a VCR model for the price of homes in Boston based on data from the 1970 U.S. census (Harrison and Rubinfeld, 1978; Gilley and Pace, 1996; Pace and Gilley, 1997). The data are the median price of homes sold in 506 census tracts (MEDV), along with the potential covariates CRIM (the per-capita crime rate in the tract), RM (the mean number of rooms for houses sold in the tract), RAD (an index of how accessible the tract is from Boston’s radial roads), TAX (the property tax per \$10,000 of property value), and LSTAT (the percentage of the tract’s residents who are considered “lower status”). With the Epanechnikov kernel, the nearest neighbors type bandwidth was set to $h = 0.26$.

The estimates of the local coefficients are plotted in the first five panels of Figure 1 and are summarized in Table 1. The estimated coefficients of CRIM and LSTAT were everywhere negative or exactly zero, suggesting that the crime rate and proportion of “lower-status” individuals were associated with a lower median house price. Meanwhile, the coefficient of RM was everywhere estimated to be positive, so the more rooms in the average house was everywhere associated with a higher median house price. The coefficient of TAX was negative in most census tracts, but was estimated to be exactly zero in 50 tracts, indicating no discernable effect of the property tax rate on house prices in those tracts. The coefficient of RAD is positive in some areas and negative in others. This indicates that there are parts of Boston where access to radial roads is associated with a greater median house price and parts where it is associated with a lesser median house price. The bottom right panel of Figure 1 shows which covariates were estimated to have a nonzero coefficient in each tract. There were 471 tracts where all LAGR estimated that all the covariates had a nonzero coefficient, 43 tracts where all covariates except for TAX were estimated to have nonzero coefficients, six tracts where the coefficients of CRIM and TAX were estimated to be zero, and one tract where the coefficients of CRIM, RAD, and LSTAT were estimated to be zero.

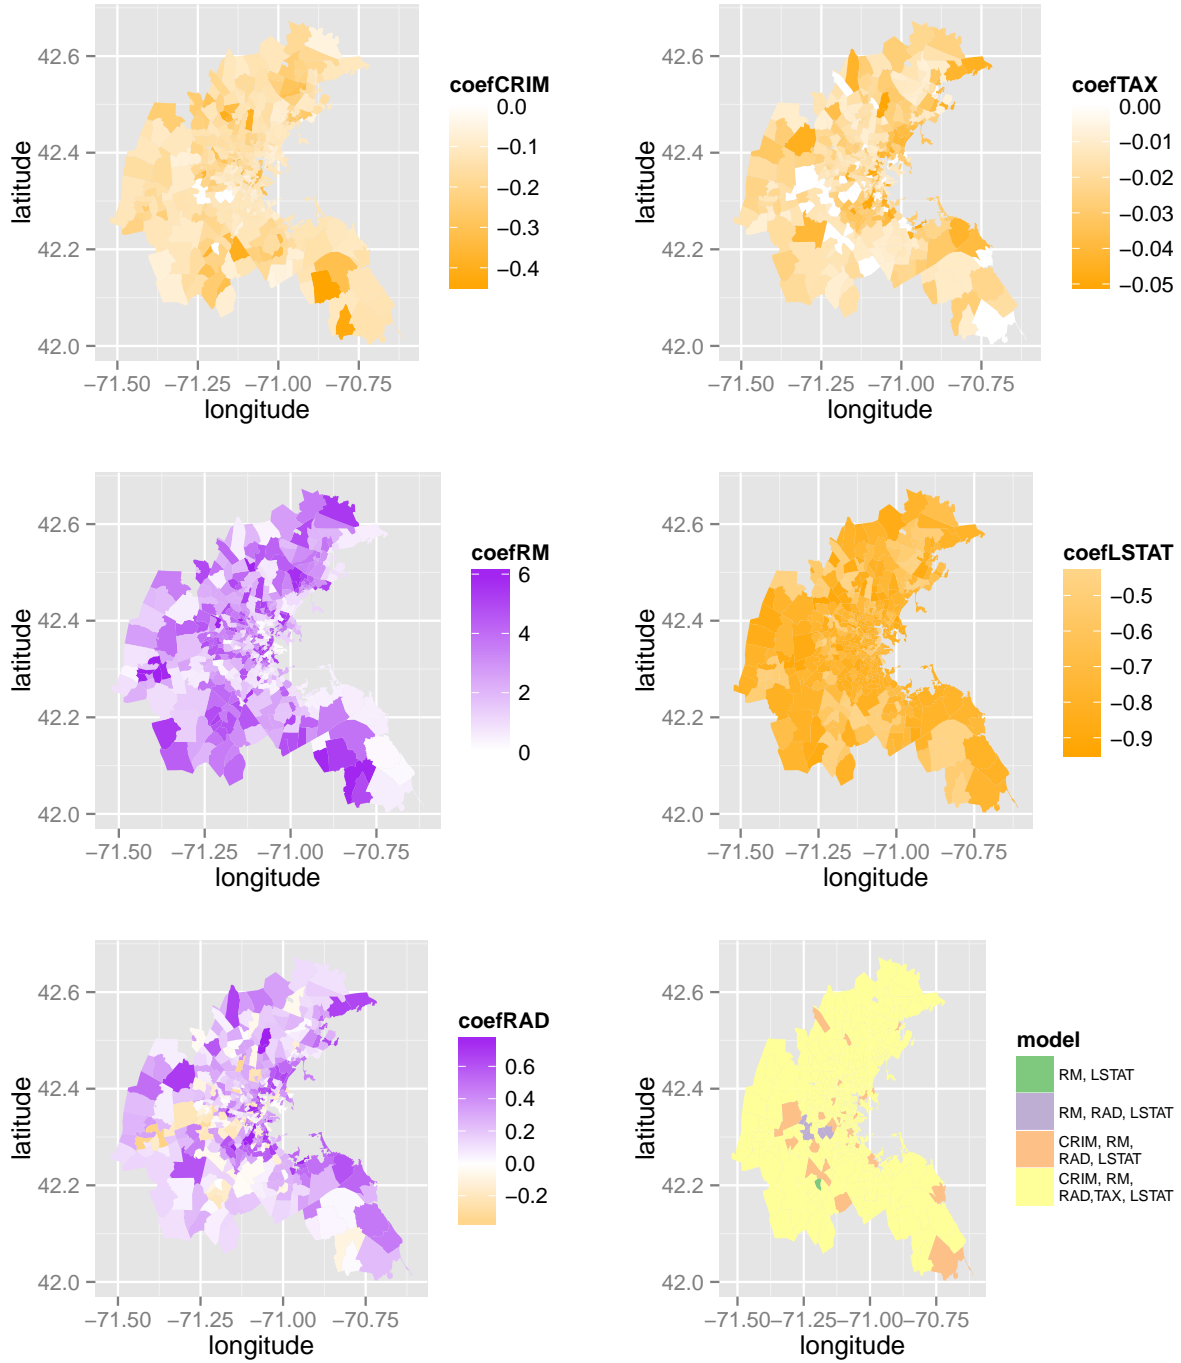

Figure 1: A varying coefficient regression model for the median house price in each census tract in Boston in 1970, estimated by local adaptive grouped regularization. In the left column are the estimated coefficients for covariates CRIM (per-capita crime rate), RM (mean number of rooms per house), and RAD (an index of access to radial roads). In the right column are the estimated coefficients for covariates TAX (property tax per \$10,000) and LSTAT (proportion of residents who are “lower status”), and a map indicating which covariates were estimated to have nonzero coefficients in each census tract.

Covariate	Mean	Standard dev.	Zero coef. count
CRIM	-0.15	0.07	7
RM	2.56	1.68	0
RAD	0.21	0.25	1
TAX	-0.02	0.01	50
LSTAT	-0.73	0.13	0

Table 1: The mean, standard deviation, and count of zeros among the estimates of the local coefficients in a model for the median house price in 506 census tracts in Boston, with coefficients selected and fitted by local adaptive grouped regularization. The covariates are CRIM (per capita crime rate in the census tract), RM (average number of rooms per home sold in the census tract), RAD (an index of the tract’s access to radial roads), TAX (property tax per USD10,000 of property value), and LSTAT (percentage of the tract’s residents who are considered “lower status”).

5. Extension to Generalized Linear Regression

5.1. Local GLM and Local Quasi-likelihood Estimation

Generalized linear models (GLMs) extend the linear regression model to a response variable following any distribution in the exponential family (McCullagh and Nelder, 1989). As is the case for the local linear regression model, we now consider local GLM coefficients as smooth functions of location (Cai et al., 2000). Suppose the response variable Y is from an exponential family distribution with $E\{y(\mathbf{s})|\mathbf{x}(\mathbf{s})\} = \mu(\mathbf{s}) = b'(\theta(\mathbf{s}))$, $\theta(\mathbf{s}) = (g \circ b')^{-1}(\eta(\mathbf{s}))$, $\eta(\mathbf{s}) = \mathbf{x}(\mathbf{s})^T \boldsymbol{\beta}(\mathbf{s}) = g(\mu(\mathbf{s}))$, $\text{Var}\{y(\mathbf{s})|\mathbf{x}(\mathbf{s})\} = b''(\theta(\mathbf{s}))$, and link function $g(\cdot)$. Then the probability density is

$$f(y(\mathbf{s})|\mathbf{x}(\mathbf{s}), \theta(\mathbf{s})) = c(y(\mathbf{s})) \times \exp\{\theta(\mathbf{s})y(\mathbf{s}) - b(\theta(\mathbf{s}))\}.$$

If $g^{-1}(\cdot) = b'(\cdot)$, then the composition $(g \circ b')(\cdot)$ is the identity function. This particular g is called the canonical link. Assuming the canonical link, all that is required is to specify the mean-variance relationship via the variance function, $V(\mu(\mathbf{s}))$. Then the local coefficients can be estimated by maximizing the local quasi-likelihood

$$\ell^*(\boldsymbol{\zeta}(\mathbf{s})) = \sum_{i=1}^n K_h(\|\mathbf{s} - \mathbf{s}_i\|) Q(g^{-1}(\mathbf{z}_i^T \boldsymbol{\zeta}(\mathbf{s})), Y_i). \quad (6)$$

The local quasi-likelihood (6) generalizes the local log-likelihood (??) that was used to estimate coefficients in the local linear regression. The local quasi-likelihood (6) is concave, and is defined in terms of its derivative, the local quasi-score function $(\partial/\partial\mu)Q(\mu, y) = (y - \mu)\{V(\mu)\}^{-1}$. The local quasi-likelihood is maximized by setting the local quasi-score function to zero:

$$(\partial/\partial\boldsymbol{\zeta})\ell^*(\hat{\boldsymbol{\zeta}}(\mathbf{s})) = \sum_{i=1}^n K_h(\|\mathbf{s} - \mathbf{s}_i\|) (y_i - \hat{\mu}(\mathbf{s}_i; \mathbf{s})) \{V(\hat{\mu}(\mathbf{s}_i; \mathbf{s}))\}^{-1} \mathbf{z}_i = \mathbf{0}_{3p}, \quad (7)$$

where $\hat{\mu}(\mathbf{s}_i; \mathbf{s}) = g^{-1}(\mathbf{z}_i^T \hat{\boldsymbol{\zeta}}(\mathbf{s}))$ is the mean at location \mathbf{s}_i evaluated at the estimated coefficients $\hat{\boldsymbol{\zeta}}(\mathbf{s})$ at location \mathbf{s} . The asymptotic distribution of the local coefficients in a varying-coefficient GLM with a one-dimensional effect-modifying parameter are given in Cai et al. (2000). For coefficients that vary in the two dimensions, the arguments in the proof of Theorem 1 of Cai et al. (2000) can be extended to show that the distribution of the estimated local coefficients is:

$$\begin{aligned} \{nh^2 f(\mathbf{s})\}^{1/2} \left[\tilde{\boldsymbol{\beta}}(\mathbf{s}) - \boldsymbol{\beta}(\mathbf{s}) - (1/2)\kappa_0^{-1}\kappa_2 h^2 \{\nabla_{uu}^2 \boldsymbol{\beta}(\mathbf{s}) + \nabla_{vv}^2 \boldsymbol{\beta}(\mathbf{s})\} \right] \\ \xrightarrow{D} N(\mathbf{0}, \kappa_0^{-2} \nu_0 \boldsymbol{\Gamma}(\mathbf{s})^{-1}). \end{aligned}$$

where $\boldsymbol{\Gamma}(\mathbf{s}) = E\{\rho(\mathbf{s}, \mathbf{X}(\mathbf{s})) \mathbf{X}(\mathbf{s}) \mathbf{X}(\mathbf{s})^T | \mathbf{s}\}$, $\rho(\mathbf{s}, \mathbf{z}) = [g_1(\mu(\mathbf{s}, \mathbf{z}))]^2 \text{Var}\{Y(\mathbf{s}) | \mathbf{X}(\mathbf{s}), \mathbf{s}\}$, $g_1(\cdot) = g'_0(\cdot)/g'(\cdot)$, and $g_0(\cdot)$ is the canonical link function. So when the canonical link is used, $\rho(\mathbf{s}, \mathbf{z}) = V(\mu(\mathbf{s}, \mathbf{z}))$.

5.2. LAGR Penalized Local Likelihood and Oracle Properties

Whereas the method of LAGR for local linear regression uses a penalized local likelihood, LAGR for GLMs uses a penalized negative local quasi-likelihood:

$$\begin{aligned}\mathcal{J}(\boldsymbol{\zeta}(\mathbf{s})) &= -\ell^*(\boldsymbol{\zeta}(\mathbf{s})) + \mathcal{P}(\boldsymbol{\zeta}(\mathbf{s})) \\ &= -\sum_{i=1}^n K_h(\|\mathbf{s} - \mathbf{s}_i\|) Q(g^{-1}(\mathbf{z}_i^T \boldsymbol{\zeta}(\mathbf{s})), Y_i) + \sum_{j=1}^p \phi_j(\mathbf{s}) \|\boldsymbol{\zeta}_{(j)}(\mathbf{s})\|.\end{aligned}$$

6. Conclusions and Discussion

We have developed a new method of LAGR and shown its oracle properties for local variable selection and coefficient estimation in VCR models. This innovation provides a natural and heretofore lacking flexibility to variable selection for varying coefficient regression models, as any covariate may be included in part of and not necessarily the entire domain of interest. This is in contrast to the existing literature on variable selection for VCR models that focuses on global variable selection, where a covariate is either included in or excluded from the model over its entire domain. Further, the method of LAGR extends the adaptive group Lasso. In particular, the previous literature on the adaptive group Lasso is insufficient for local selection in a VCR model because the local weights are functions of the kernel $K(\cdot)$ and the bandwidth h . As a result, the local observation weights change with sample size and the coefficient estimates converge at a slower rate than in the traditional adaptive group Lasso. Under our refined conditions, we have established the oracle property for the LAGR method.

Here we have considered the case of two-dimensional effect-modifying parameter. Similar results can be obtained when the effect-modifying parameter has dimension other than two, but in higher dimensions the so-called “curse of dimensionality” means that the estimation

accuracy may quickly degrade. Since the optimal rate of convergence for nonparametric regression is achieved when $h = O\left(n^{-1/\{4+d\}}\right)$ where d is the dimension of the effect-modifying parameter, it follows that to attain the oracle properties, the exponent in the adaptive weights for LAGR estimation must satisfy $\gamma > d/2$.

A possible future direction to take is extension to local regression for spatio-temporal data such that the regression coefficients vary not only in space but also over time. This extension is left to future research.

Appendix A. Proofs of Theorems 3–4

Proof of Theorem 1

The next proofs require the lemmas in the web-based supplemental material. First, let $\mathbf{z} \in \mathbb{R}^{3p}$. Define the q -functions to be the derivatives of the quasi-likelihood: $q_j(t, y) = (\partial/\partial t)^j Q(g^{-1}(t), y)$. Then $q_1(\eta(\mathbf{s}, \mathbf{z}), \mu(\mathbf{s}, \mathbf{z})) = \mathbf{0}$, and $q_2(\eta(\mathbf{s}, \mathbf{z}), \mu(\mathbf{s}, \mathbf{z})) = -\rho(\mathbf{s}, \mathbf{z})$. Let

$$\tilde{\beta}_i'' = \left[(\mathbf{s}_i - \mathbf{s})^T \{ \nabla^2 \beta_1(\mathbf{s}) \} (\mathbf{s}_i - \mathbf{s}), \dots, (\mathbf{s}_i - \mathbf{s})^T \{ \nabla^2 \beta_p(\mathbf{s}) \} (\mathbf{s}_i - \mathbf{s}) \right]^T$$

be the p -vector of quadratic forms of location interactions on the second derivatives of the coefficient functions.

Proof. Let $H'_n(\mathbf{u}) = \mathcal{J}^*(\zeta(\mathbf{s}) + \alpha_n \mathbf{u}) - \mathcal{J}^*(\zeta(\mathbf{s}))$ and $\alpha_n = h^{-1}n^{-1/2}$. Then, minimizing $H'_n(\mathbf{u})$ is equivalent to minimizing $H_n(\mathbf{u})$, where

$$\begin{aligned} H_n(\mathbf{u}) &= -n^{-1} \sum_{i=1}^n Q(g^{-1}(\mathbf{Z}_i^T \{\zeta(\mathbf{s}) + \alpha_n \mathbf{u}\}), Y_i) K(h^{-1}\|\mathbf{s} - \mathbf{s}_i\|) \\ &\quad + n^{-1} \sum_{i=1}^n Q(g^{-1}(\mathbf{Z}_i^T \zeta(\mathbf{s})), Y_i) K(h^{-1}\|\mathbf{s} - \mathbf{s}_i\|) \\ &\quad + n^{-1} \sum_{j=1}^p \phi_j(\mathbf{s}) \|\zeta_{(j)}(\mathbf{s}) + \alpha_n \mathbf{u}\| - \sum_{j=1}^p \phi_j(\mathbf{s}) \|\zeta_{(j)}(\mathbf{s})\|. \end{aligned}$$

Define

$$\Omega_n = \alpha_n \sum_{i=1}^n q_1(\mathbf{Z}_i^T \zeta(\mathbf{s}), Y_i) \mathbf{Z}_i K(h^{-1}\|\mathbf{s} - \mathbf{s}_i\|) = \alpha_n \sum_{i=1}^n \omega_i$$

and

$$\Delta_n = -\alpha_n^2 \sum_{i=1}^n q_2(\mathbf{Z}_i^T \zeta(\mathbf{s}), Y_i) \mathbf{Z}_i \mathbf{Z}_i^T K(h^{-1}\|\mathbf{s} - \mathbf{s}_i\|) = \alpha_n^2 \sum_{i=1}^n \delta_i.$$

Then it follows from the Taylor expansion of $\mathcal{J}^*(\zeta(\mathbf{s}) + \alpha_n \mathbf{u})$ around $\zeta(\mathbf{s})$ that

$$\begin{aligned} H_n(\mathbf{u}) = & -\Omega_n^T \mathbf{u} + (1/2) \mathbf{u}^T \Delta_n \mathbf{u} + (\alpha_n^3/6) \sum_{i=1}^n q_3 \left(\mathbf{Z}_i^T \tilde{\zeta}_i, Y_i \right) [\mathbf{Z}_i^T \mathbf{u}]^3 K(h^{-1} \|\mathbf{s} - \mathbf{s}_i\|) \\ & + \sum_{j=1}^p \phi_j(\mathbf{s}) \left\{ \|\zeta_{(j)}(\mathbf{s}) + h^{-1} n^{-1/2} \mathbf{u}\| - \|\zeta_{(j)}(\mathbf{s})\| \right\}. \end{aligned} \quad (\text{A.1})$$

where $\tilde{\zeta}_i$ lies between $\zeta(\mathbf{s})$ and $\zeta(\mathbf{s}) + \alpha_n \mathbf{u}$. Since $q_3(\mathbf{Z}_i^T \tilde{\zeta}_i, Y_i)$ is linear in Y_i , $K(\cdot)$ is bounded, and, by condition (C.6),

$$(\alpha_n^3/6) E \left| \sum_{i=1}^n q_3 \left(\mathbf{Z}_i^T \tilde{\zeta}_i, Y_i \right) [\mathbf{Z}_i^T \mathbf{u}]^3 K(h^{-1} \|\mathbf{s} - \mathbf{s}_i\|) \right| = O(\alpha_n),$$

the third term in (A.1) is $O_p(\alpha_n)$. The limiting behavior of the last term of (A.1) differs between the cases $j \leq p_0(\mathbf{s})$ and $j > p_0(\mathbf{s})$. *Case $j \leq p_0(\mathbf{s})$:* If $j \leq p_0(\mathbf{s})$, then $n^{-1/2} \phi_j(\mathbf{s}) \rightarrow n^{-1/2} \lambda_n \|\zeta_{(j)}(\mathbf{s})\|^{-\gamma}$ and $|\sqrt{n} \{ \|\zeta_{(j)}(\mathbf{s}) + \alpha_n \mathbf{u}_{(j)}\| - \|\zeta_{(j)}(\mathbf{s})\| \}| \leq h^{-1} \|\mathbf{u}_{(j)}\|$. Thus,

$$\lim_{n \rightarrow \infty} \phi_j(\mathbf{s}) (\|\zeta_{(j)}(\mathbf{s}) + \alpha_n \mathbf{u}_{(j)}\| - \|\zeta_{(j)}(\mathbf{s})\|) \leq \alpha_n \phi_j(\mathbf{s}) \|\mathbf{u}_{(j)}\| \leq \alpha_n a_n \|\mathbf{u}_{(j)}\| \rightarrow 0$$

Case $j > p_0(\mathbf{s})$: If $j > p_0(\mathbf{s})$, then $\phi_j(\mathbf{s}) (\|\zeta_{(j)}(\mathbf{s}) + \alpha_n \mathbf{u}_{(j)}\| - \|\zeta_{(j)}(\mathbf{s})\|) = \phi_j(\mathbf{s}) \alpha_n \|\mathbf{u}_{(j)}\|$. Since $h = O(n^{-1/6})$, if $h n^{-1/2} b_n \xrightarrow{p} \infty$, then $\alpha_n b_n \xrightarrow{p} \infty$. Now, if $\|\mathbf{u}_{(j)}\| \neq 0$, then

$$\alpha_n \phi_j(\mathbf{s}) \|\mathbf{u}_{(j)}\| \geq \alpha_n b_n \|\mathbf{u}_{(j)}\| \rightarrow \infty.$$

On the other hand, if $\|\mathbf{u}_{(j)}\| = 0$, then $\alpha_n \phi_j(\mathbf{s}) \|\mathbf{u}_{(j)}\| = 0$. By Lemma 1, $\Delta_n = \Delta + O_p(\alpha_n)$, so the limit of $H_n(\mathbf{u})$ is the same as the limit of $H_n^*(\mathbf{u})$ where

$$H_n^*(\mathbf{u}) = -\Omega_{(a)n}^T \mathbf{u}_{(a)} + (1/2) \mathbf{u}_{(a)}^T \Delta_{(a)} \mathbf{u}_{(a)} + o_p(1)$$

if $\|\mathbf{u}_j\| = 0 \forall j > p_0(\mathbf{s})$, and $H_n^*(\mathbf{u}) = \infty$ otherwise. It follows that $H_n^*(\mathbf{u})$ is convex and has a unique minimizer, called $\hat{\mathbf{u}}_n$. Let $\hat{\mathbf{u}}_{(a)n}$, $\Delta_{(a)}$ and $\Omega_{(a)n}$ be, respectively, the parts of \mathbf{u}_n , Δ ,

and Ω_n corresponding to the true nonzero coefficients, and let $\hat{\mathbf{u}}_{(b)n}$ be the subvector of $\hat{\mathbf{u}}_n$ corresponding to the true zero coefficients. Then

$$\hat{\mathbf{u}}_{(a)n} = \Delta_{(a)}^{-1} \Omega_{(a)n} + o_p(1) \text{ and } \hat{\mathbf{u}}_{(b)n} = \mathbf{0}$$

by the quadratic approximation lemma (Fan and Gijbels, 1996). By epiconvergence, the minimizer of the limiting function is the limit of the minimizers $\hat{\mathbf{u}}_n$ (Geyer, 1994; Knight and Fu, 2000). Since Δ is a constant, the normality of $\hat{\mathbf{u}}_{(a)n}$ follows from the normality of Ω_n , which is established via the Cramér-Wold device. Let $\mathbf{d} \in \mathbb{R}^{3p}$ be a unit vector, and let

$$\xi_i = q_1 \left(\mathbf{Z}_i^T \boldsymbol{\zeta}(\mathbf{s}), Y_i \right) \mathbf{d}^T \mathbf{Z}_i K \left(h^{-1} \|\mathbf{s}_i - \mathbf{s}\| \right).$$

Then $\mathbf{d}^T \Omega_n = \alpha_n \sum_{i=1}^n \xi_i$. We establish the normality of $\mathbf{d}^T \Omega_n$ by checking the Lyapunov condition of the sequence $\left\{ \mathbf{d}^T \text{Var}(\Omega_n) \mathbf{d} \right\}^{-1/2} \left\{ \mathbf{d}^T \Omega_n - \mathbf{d}^T E \Omega_n \right\}$. By boundedness of $K(\cdot)$, linearity of $q_1(\mathbf{Z}_i^T \boldsymbol{\zeta}(\mathbf{s}), Y_i)$ in Y_i , and conditions (C.6) and (C.8), we have that

$$n \alpha_n^3 E(|\xi_1|^3) = O(\alpha_n) \rightarrow 0. \quad (\text{A.2})$$

We observe that (A.2) implies that $n \alpha_n^3 |E(\xi_1)|^3 \rightarrow 0$, and since $E(|\xi_1 - E\xi_1|^3) < E\{(|\xi_1| + |E\xi_1|)^3\} \rightarrow 0$, the Lyapunov condition is satisfied. Thus, Ω_n asymptotically follows a Gaussian distribution and the result follows from the quadratic approximation lemma. \square

Proof of Theorem 2

Proof. The proof is by contradiction. Without loss of generality we consider only the p th covariate group. Assume $\|\hat{\boldsymbol{\zeta}}_{(p)}(\mathbf{s})\| \neq 0$. Then $\mathcal{J}(\boldsymbol{\zeta}(\mathbf{s}))$ is differentiable w.r.t. $\boldsymbol{\zeta}_{(p)}(\mathbf{s})$ and is minimized where

$$\phi_p(\mathbf{s}) \hat{\boldsymbol{\zeta}}_{(p)}(\mathbf{s}) \|\hat{\boldsymbol{\zeta}}_{(p)}(\mathbf{s})\|^{-1} = \sum_{i=1}^n q_1 \left(\mathbf{Z}_i^T \hat{\boldsymbol{\zeta}}(\mathbf{s}), Y_i \right) \mathbf{Z}_{i(p)} K \left(h^{-1} \|\mathbf{s}_i - \mathbf{s}\| \right) \quad (\text{A.3})$$

From Lemma 2, the right hand side of (A.3) is $O_p(1)$, so for $\hat{\boldsymbol{\zeta}}_{(p)}(\mathbf{s})$ to be a solution, we must have that $hn^{-1/2}\phi_p(\mathbf{s})\hat{\boldsymbol{\zeta}}_{(p)}(\mathbf{s})\|\hat{\boldsymbol{\zeta}}_{(p)}(\mathbf{s})\|^{-1} = O_p(1)$. But since by assumption $\hat{\boldsymbol{\zeta}}_{(p)}(\mathbf{s}) \neq \mathbf{0}$, there must be some $k \in \{1, 2, 3\}$ such that $|\hat{\zeta}_{(p)k}(\mathbf{s})| = \max\{|\hat{\zeta}_{(p)m}(\mathbf{s})| : 1 \leq m \leq 3\}$. And for this k , we have that $|\hat{\zeta}_{(p)k}(\mathbf{s})|\|\hat{\boldsymbol{\zeta}}_{(p)}(\mathbf{s})\|^{-1} \geq 3^{-1/2} > 0$. Since $hn^{-1/2}b_n \rightarrow \infty$, we have that $hn^{-1/2}\phi_p(\mathbf{s})\hat{\boldsymbol{\zeta}}_{(p)}(\mathbf{s})\|\hat{\boldsymbol{\zeta}}_{(p)}(\mathbf{s})\|^{-1} \geq hb_n(3n)^{-1/2} \rightarrow \infty$ and therefore the left hand side of (A.3) dominates the sum to the right side. Thus, for large enough n , $\hat{\boldsymbol{\zeta}}_{(p)}(\mathbf{s}) \neq \mathbf{0}$ cannot maximize $\mathcal{J}(\cdot)$, and therefore $P\left\{\hat{\boldsymbol{\zeta}}_{(b)}(\mathbf{s}) = \mathbf{0}\right\} \rightarrow 1$. \square
